## 1. INTRODUCTION

This report summarizes the results of research and software tool development aimed at making parallel processing much easier and less error-prone. The approach we have demonstrated involves developing scientific application programs using a high-level parallel model (Large-Grain Data Flow or LGDF). Programs written in the LGDF framework have been transformed into appropriate source code for a variety of sequential, vector, and parallel machines [1] [2] [3].

We based the tool development for this project on a set of prototype LGDF implementation tools based on macro-expansion techniques. As part of the current project, these existing software tools were modified to generate parallel scheduling mechanisms that implement the LGDF model efficiently on the HEP. To demonstrate the use of the tools, for parallel processing, we transformed a sequential Monte Carlo code (GAMTEB) into an LGDF code capable of either sequential or parallel operation via a series of transformation steps.

Section 2 of this report presents an overview of the Large-Grain Data Flow model, and the way it was implemented on the HEP.

Section 3 discusses our adventures in getting the original sequential GAMTEB to run correctly on a VAX running Berkeley 4.2 Unix. (This proved to be a surprisingly difficult job, and in fact was more difficult than parallelizing the sequential code

after it was runnable on the VAX) .

In Section 4, modifications to sequential GAMTEB in anticipation of parallel operation are discussed. These modifications allowed more highly parallel operation, and resulted in a single process code directly comparable to the LGDF multi-process version.

In Section 5, we present the rationale for the LGDF partitioning of the processes and data structures within GAMTEB, as well as a discussion of some minor modifications to the code required to meet LGDF standards. We also summarize our experiences in debugging the LGDF (sequential) code.

In Section 6, we discuss some further changes and bugfixes in the LGDF macros that became apparent when we actually ran the LGDF model in parallel under the HEP Unix Parallel Executive (UPX). The problems were not "GAMTEB" problems, but LGDF macro problems caused by the shift to HEP/UPX. They were not difficult to fix, but tracking them down in a parallel program was, as usual, quite difficult.

Section 7 presents a summary of our results and recommendations for further research.

## 2. OVERVIEW OF LARGE-GRAIN DATA FLOW

The Large Grain Data Flow (LGDF) approach is based on viewing programs as being made up of systems of data-activated processing

units. Using a coherent hierarchy of data flow diagrams, complex systems are specified as compositions of simpler systems. The lowest level processing units correspond roughly to FORTRAN SUBROUTINE's[\*].

The steps involved in modeling and implementing a FORTRAN code using the LGDF computation model and tools are as follows:

- 1) Draw Data Flow Diagrams- create a hierarchical, consistent set of system data flow diagrams that express the logical data dependencies of the program or problem modeled.
- 2) Create Wirelist- encode the data flow dependencies of the set of data flow diagrams using macro calls.
- 3) Package Data Declarations- identify and cluster the FORTRAN data declarations corresponding to each data link in the system data diagrams. (These will become a set of labeled COMMON declarations in the generated programs).
- 4) Add Data Flow Control to Program Fragments- embed standard data flow control macro calls in the FORTRAN code.

---

[\*] These lowest level programs are "large-grained." This means that the amount of processing that a lowest level routine performs each time it executes is large compared to the overhead of scheduling its execution. On the DENELCOR HEP computer the mechanism needed for data-activated execution scheduling is built-in to the hardware, allowing efficient execution even for "fine-grained" programs.

- 5) Expand Data Flow Macros- macro expand the wirelist, packaged data declarations, and program fragments to produce compilable FORTRAN for the particular machine desired (in this case, either the VAX Unix 4.2, or the HEP/UPX) [\*].
- 6) Compile and Execute- including if desired, pre- and/or post-compilation optimization steps available for the particular target environment.

More details on Large-Grain Data Flow and its implementation on the HEP can be found in [4] [5] and in the paper [6] (a preprint of a book chapter written as part of this work, included in this report as Appendix A).

### 3. PORTING SEQUENTIAL GAMTEB TO THE VAX

The changes made to the original, sequential version of GAMTEB to get it to compile on the VAX (running under Berkeley 4.2bsd UNIX with the f77 compiler) were of several major types:

- 1) changes for FORTRAN77
- 2) VAX-specific changes
- 3) Library subroutine differences

---

[\*]We use the standard Unix general purpose macro processor "m4" for the current version of the LGDF macros. For HEP-OS, programs were macro expanded under Unix, and the resulting source code transmitted to the HEP for compilation and execution. The macros have now also been run successfully under HEP/UPX.

The next step was to get GAMTEB running correctly. This involved tracking down and fixing a serious bug caused by the equivalence of reals and integers. Finally, a portable random number generator was installed to insure that results would be identical on the HEP and the VAX.

A summary of the changes is given below. The notation [original-line#] refers to line numbers in the original, sequential GAMTEB (Appendix B). The reference [f77-line#] is to line numbers in the sequential version of GAMTEB as modified to get running under 4.2 (Appendix C). The notations [lgdf-d# line#] [lgdf-p# line#] refer to the Large-Grain Data Flow version (Appendix D):

- 1) The PROGRAM line was changed from:

PROGRAM GAMTEB (OUTPUT, TAPE4=OUTPUT) [original-3]

to:

PROGRAM GAMTEB [f77-4]

- 2) Non-standard multiple assignment statements, for example:

IF (J.EQ.JA) D2=D1=-2.\*A1 [original-373]

was changed to:

IF (J.EQ.JA) THEN [f77-427 to 430]  
D1=-2.\*A1  
D2=-2.\*A1  
END IF

(see also [original-403] and [f77-461 to 464]).

- 3) The machine-dependent subroutine 'SECOND' was replaced by a dummy version:

```
SUBROUTINE SECOND (T) [f77-573 to 576]
T=0
RETURN
END
```

- 4) The following variable names were reduced to six characters:

```
ESCAPE2 --> ESCAP2      see for example [f77-24]
ESCAPEI --> ESCAPI      [f77-25]
RESCAPE --> RESCAP      [f77-27]
```

- 5) The number of particles was reduced so that GAMTEB would run on the VAX in a reasonable length of time. That is,

NPP=500000 [original-46]  
was changed to:

NPP=100 [f77-67]

- 6) "Almost underflow" exponents -123 to -37 were changed to fit into the exponent range of the VAX F\_floating data type (32 bit), for example:

IF (XPP(I).EQ.0.) XPP(I)=1.OE-123 [original-38]  
was changed to:  
IF (XPP(I).EQ.0.) XPP(I)=1.OE-37 [f77-57]  
(see also [original-39] and [f77-59]).

7) A real variable was initialized with an integer constant:

FIM(1)=1 [original-72]

and for stylistic reasons was changed:

FIM(1)=1.0 [f77-103]

8) An extra initialization of the variable INBNK was removed:

INBNK=0 [original-74]

changed to:

C INBNK=0 [f77-106]

9) The real-integer equivalencing problem related to banking particle values was fixed. In the original version of GAMTEB, a real array (BANK) and an integer array (IBANK) were equivalenced. Another array (PBL) was equivalenced to a series of variables in COMMON which included two integers (IA and NP) :

```
COMMON X,Y,Z,U,V,W,ERG,IA,WT,NP           from [original-8]
DIMENSION BANK(100,10),PBL(10),IBANK(100,10)   from [original-12]
EQUIVALENCE (PBL,X),(BANK,IBANK)                [original-14]
```

This bug showed up because when moving a floating point number, the VAX hardware changes an F\_floating datum with an exponent value of 0 (bits 14:7) and a sign bit of 0 (bit 15) to the value 0 by zapping any other "dirty zero" bits. Thus,

real to real assignments between arrays equivalenced to integer values often resulted in the loss of the integer values!

The problem was solved by creating new arrays and only equivalencing arrays of the same data type, and then modifying the pertinent sections of the code:

```
COMMON X,Y,Z,U,V,W,ERG,WT,IA,NP [f77-9]
DIMENSION BANK(100,8),PBL(8),IBANK(100,2),IPBL(2) [f77-29]
EQUIVALENCE (PBL,X),(IPBL,IA) [f77-30]
```

(See also [f77-197 to 200, 204 to 207, and 209 to 210]).

NOTE: This was a very difficult problem to track down.

- 10) Random number generators. GAMTEB was first run with a dummy random number generator which always returned the constant 0.5. (By the choice of the constant 0.5 it was also discovered by accident that any random number generator that returns two consecutive 0.5's will cause GAMTEB to blow up in subroutine ISOS during the computation of T3 (!):

```
T1=2.*RANF (KRN)-1. [f77-528 to 533]
T2=2.*RANF (KRN)-1.
RSQ=T1**2+T2**2
U=2.*RSQ-1.
T3=SQRT((1.-U**2)/RSQ)
```

- 11) Next, GAMTEB was run using the UNIX random number generator RAND. Later, a more portable random number generator (suggested by Paul Frederickson) was installed:

```
REAL FUNCTION RANF (KERN)
KERN = MOD(1+9621*KERN,131072)
RANF = FLOAT(KERN)/131072.
RETURN
END
```

[f77-584 to 588]

- 12) The resulting program was run on both the VAX and the HEP (as a sequential code for 100 particles, producing the same output.

#### 4. MODIFICATIONS TO SEQUENTIAL GAMTEB FOR PARALLEL OPERATION

This section describes changes to the original GAMTEB necessary to allow deterministic parallel computation of the histories of separate particles and their descendants. This was done with the addition of a second random number sequence generator. In the modified method, new particles are started with random seeds from the first sequence, and the history of that particle and its daughter particles is simulated using that seed and the second random number generator.

The rationale for this is as follows. Using only one random number generator results in an inherent sequential bottleneck. If we try to run particle histories in parallel, each process concurrently running a history would be competing for the next random number. In order to have a deterministic program, a process would have to completely finish its particle history before the next process could be allowed to compete for its random

numbers. In any case, the potential parallelism would be greatly reduced.

- 1) In the original GAMTEB, the state of the random number generator was kept inside the random number generation routine RANF. The value of the argument to RANF, KRN, was not used as an input to the random number generator. (It relied on its retained value from its last use) as in:

S = -ALOG(RANF(KRN))/XST

[original-121]

This method causes problems when calling the random number generator from a variety of subroutines and functions that do not "remember" the last random number generated. Therefore, the returned value was also placed in COMMON to communicate this "latest value":

COMMON /NEW/ KRN

[f77-17]

This only needed to be done for "KRN", the returned value of the added (second) random number generator, because all calls to the first random number generator occur in the same routine.

(see also [f77-404, 483, 526 and 552])

- 2) A second portable random number generator was added:

```
REAL FUNCTION RANDO(KERN)
KERN = MOD(1+7421*KERN,131072)
RANDO = FLOAT(KERN)/131072.
RETURN
END
```

[f77-578 to 582]

This function provides a seed for the random numbers generated by RANE (see above) that are needed to run one particle history.

(see also [original-55], [f77-81], and [f77-133 to 135])

The resulting program was run on both the VAX and the HEP with 100 particles and yielded equivalent results (Appendix F).

##### 5. DEVELOPMENT OF A PSEUDO-PARALLEL LGDF VERSION OF GAMTEB

The first step in creating the LGDF model of GAMTEB was to identify problem constants. The constants were initialized in the original version both via a BLOCK DATA subprogram (for variables in labeled COMMON) and via assignment statements. These were identified as the following datapaths in the LGDF model:

d03- (problem constants)  
d04- (converted cross section tables)  
d05- (source values)

[f77-13, 19, 33 to 37]  
[f77-21, 39 to 51]  
[f77-9]

Statements that initialize these values were packaged as the LGDF process:

p10- (set up problem constants)

[f77-53 to 63, 70 to 71,  
77, 83 to 86, 102 to 104,  
121 to 129, and 131]

The LGDF network with the result of this level of data flow analysis for GAMTEB is shown in Fig. 1.

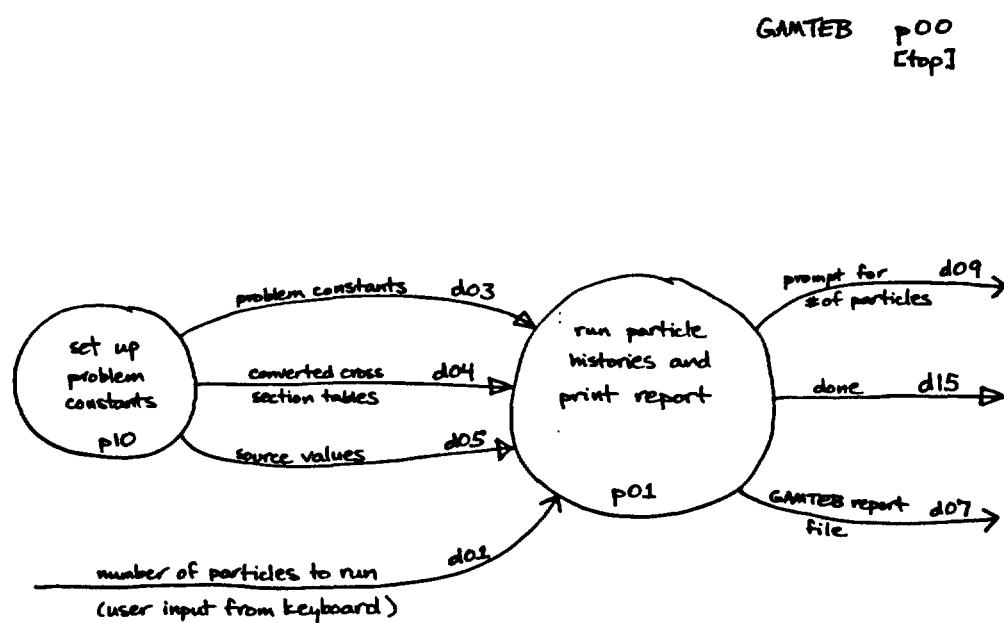

Fig. 1. An LGDF network for p00- (GAMTEB).

In the original GAMTEB, the number of particle histories to be run was initialized via an assignment statement:

C           INITIALIZE PROBLEM INPUT                                 [original-45 to 46]  
NPP=500000

We decided as part of the improvements we were making to allow this value to be specified interactively. The prompt for user input and the user response are shown on Figure 2 as d09- (prompt for # of particles) and d01- (# of particles to run). (The code for the LGDF process p12- (init GAMTEB run parameters) as well as the other process and datapath definitions can be found in Appendix D.)

To assist in running particle histories independently, we divided the particle statistics accumulators into two groups, global and local. The global accumulators are shown on Fig. 2 as d06- (run statistics), and these are initialized once per run by p12.

The process p13- (set up for particle counting) initializes various counters for use by other LGDF processes. The counters are part of the LGDF datapaths:

d11- (particle completion control)  
d12- (particle start control) and  
d10- (particle count for report)

The LGDF process p13 also initializes the value (KRN2 on d12) used to seed the first random number generator (RANDO in p16.m).

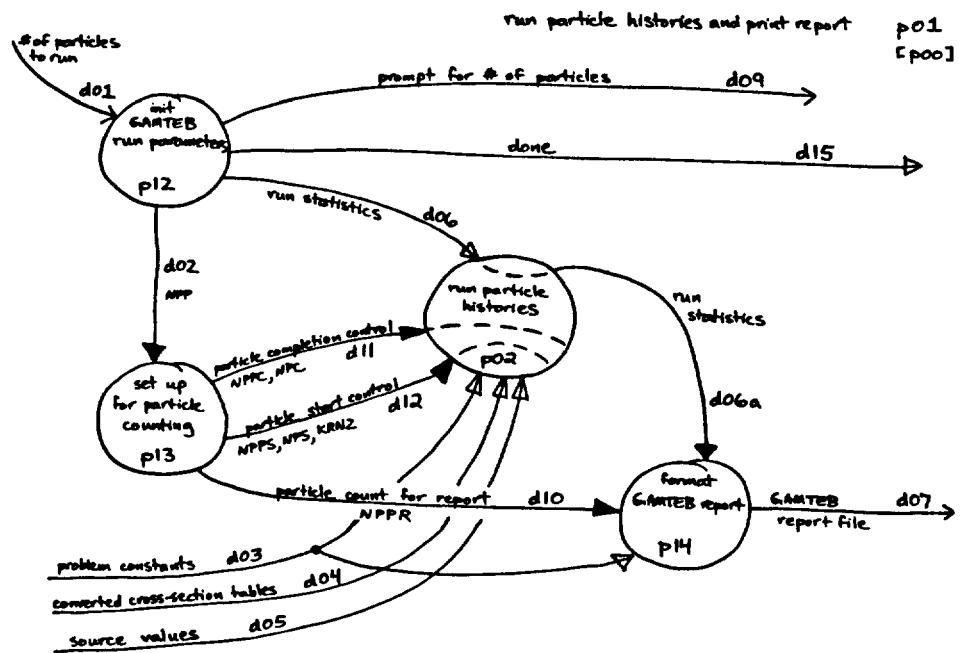

Fig. 2. LGDF network for p01- (run particle histories and print report) .

The statements that generate the report produced by GAMTEB (see [f77-294 to 295, and 298 to 389]) have been packaged as p14- (format GAMTEB report). The process p14 does some summary computations, and formats and writes the report based on the final run statistics (d06a).

The actual work of running particle histories involves three LGDF processes:

p16- (generate random seed for next particle)  
 p17- (run history for one particle and descendants) and  
 p18- (check for completion)

The LGDF network for this level is shown in Fig. 3.

The process p16 uses the function RANDO to generate a random seed for use by the second random number generator (RANF) in running the next particle history.

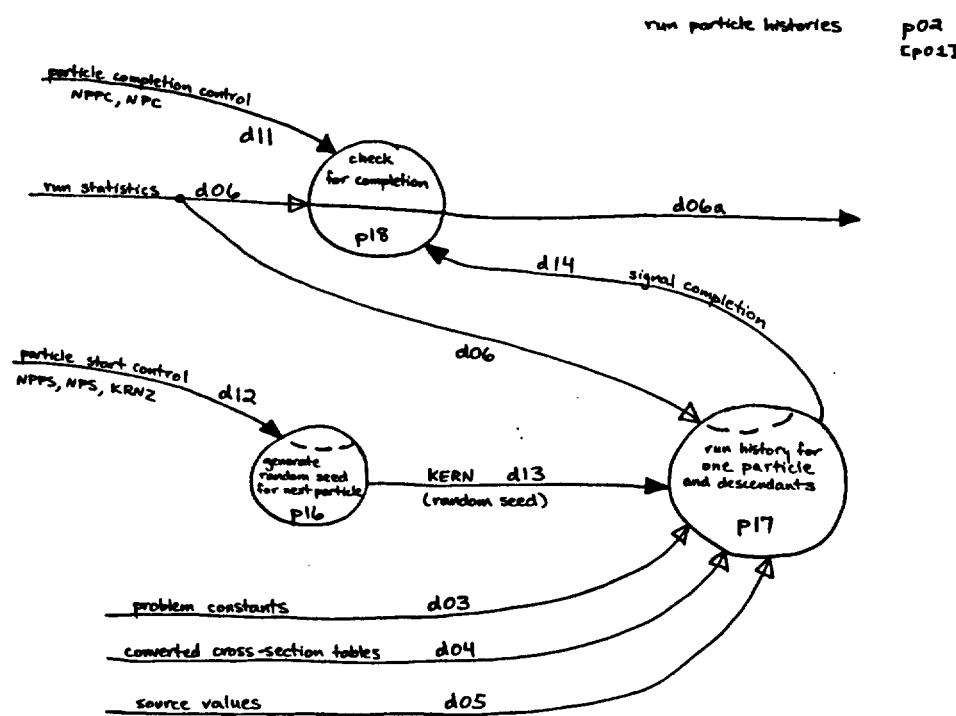

Fig. 3. LGDF network for p02- (run particle histories) .

The bulk of the original GAMTEB code (approx. 300 lines) was put mostly unchanged into p17- (run history for one particle and descendants). This process simulates the history for a particle and its daughter particles, using a local particle bank (BANK(100,8) and IBANK(100,2)). It also makes local copies of the initial source values in d05 to avoid extensive variable renaming within p17. The random seed (d13- (KERN)) received from p16 is also copied into a local variable to allow p16 to generate the random seed for the next particle as soon as possible. This does not aid sequential processing, but is the key idea that allows overlapped (parallel) computation between independent particle histories. Run statistics for each new particle and its descendants are kept in variables local to p17.

The only other major addition to the original GAMTEB code required was code to gain exclusive write access to the global accumulators d06a- (run statistics) so that multiple instances of p17 can be run in parallel with each other (see [lgdf-p17.m 197 to 206]).

The process p18- (check for completion) waits until all particle histories are completed, then signals the report-writing process, p14 by "setting" d06a- (run statistics).

#### Implementation Details

A file is used to specify the target architecture and language (both C and FORTRAN are currently supported). An example

"project" file is shown in Part 1 of Appendix D. The macro-encoded network diagrams for GAMTEB (corresponding to p00, p01, and p02 in Figures 1-3 and also in Part 2 of Appendix D) is shown in "wirelist" form in Part 3 of Appendix D. A data dictionary describing the meanings for global data values is given in Part 4, the FORTRAN data declarations are given in Part 5, and process definitions in Part 6, of Appendix D.

#### Debugging the Large-Grain Data Flow version

- 1) To avoid shared variable conflicts (shared memory synchronization problems) between multiple invocations of the subroutines called by multiple copies of p17, all inputs and outputs of those subroutines were removed from COMMON and made into subroutine arguments. (If this were not done, those subroutines would not be re-entrant, and non-determinism would likely result). While manually moving arguments of subroutine TRACK [lgdf-p17.m 228-300] out of COMMON, one result argument (DLS) was inadvertently not added to the parameter list for TRACK.

This error resulted in an arithmetic exception (floating point overflow). Fortunately, the problem was diagnosed almost immediately, thus avoiding yet another grueling session with dbx (the 4.2 Unix symbolic debugger). This was the only error that prevented the LGDF version from running, although running correctly took a little more work.

At [lgdf-p17.m 228]:

SUBROUTINE TRACK(IA,JA,X,Y,Z,U,V,W,CL,CL2,CRAD2)

was changed to:

SUBROUTINE TRACK(IA,JA,X,Y,Z,U,V,W,CL,CL2,CRAD2,DLS)

- 2) Data flow bubbles p16 and p18 were incorrectly coordinated, causing abnormal termination. The symptom was that output was not being written, indicating that p14 was not waking up. Examination of the "LGDF trace file", which optionally traces all data flow actions during a run, made it very easy to locate the problem. From the file, it was clear that p14 was lacking only the d06a input. This directed suspicion to p18, which is supposed to set d06a. The trace file also showed that p16 and p17 were coordinating their activities correctly. The conclusion was that p18 was not running correctly during its last execution cycle. Examination of the code showed that p18 was off by one on its count of particles. The inequality in:

IF (NPC.GT.NPPC) THEN

[lgdf-p18.m 5]

was changed to:

IF (NPC.GE.NPPC) THEN

The data flow control now worked correctly, and (incorrect) output was produced.

- 3) The output produced by sequential LGDF GAMTEB now consisted almost entirely of zeros, and the subsequent debug session pointed to a problem with the random number generation. By checking the code for p16 and p17, an error in variable identifiers on d13 was found. The global variable KERN, used to supply a seed for use in local random number generation had been confused with the local variable KRN. The result was that the variable in LGDF data definition file d13 did not agree with the name used in the actual code.

Several minor corrections were necessary:

- a) In [lgdf-d13] the incorrect global variable declaration:

INTEGER KRN

was changed to:

INTEGER KERN

- b) At [lgdf-p16.m 11] the local name (KRN) :

KRN = KRN2

was changed to:

KERN = KRN2

- c) At [lgdf-p17.m 15], the declaration of the local variable:

INTEGER KERN

was changed to:

INTEGER KRN

At this point, a large portion of the output was correct.

- 4) The next bug fixed was in the LGDF data definition file. The variables in d11 did not agree with the names used in the

actual code.

- 5) Another problem was that the global variables in d06 [lgdf-d06] were not updated in p17. As a result, the corresponding values in the output were all zero. The correction involved simply adding the updates, for example:

IGNCOL=IGNCOL+NCOL [lgdf-p17.m 197]

(see also [lgdf-p17.m 198 to 206])

- 6) The variable ABSORB was not reset to zero in p17. This resulted in a value of ABSORB in the output that was much too large. The cause was easy to find, and the necessary line of code was added:

ABSORB=0 [lgdf-p17.m 41]

- 7) The resulting program was run on the VAX with 100 particles and produced the same output as the f77 version described in the previous section.

## 6. PARALLEL LGDF GAMTEB FOR THE HEP UNDER UPX

Several problems arose associated with getting the parallel LGDF version of GAMTEB running under HEP/UPX.

- 1) The LGDF process p17- (run history for one particle and descendants) needs to get exclusive update access to d06a in

order to add in the statistical contribution of a particle and its daughter particles. Previously, no LGDF facility existed to "give back" exclusive access to either an input or an output in any way other than by clearing or setting. Therefore, two new macros were added to the LGDF process pseudo-functions: unread\_ and unwrite\_. An example of the use of the unread\_ macro can be found in p17 at [lgdf-p17.m 222].

- 2) The LGDF macros were not generating EXTERNAL declarations for processes that were created. This was initially handled by adding the EXTERNAL declarations manually. Fixing the LGDF macros took about an hour. See for example [lgdf-p00.f 376 to 378].
- 3) When the self-scheduled LGDF version of GAMTEB was first run in parallel on the HEP (initially at Argonne because the Los Alamos HEP was unavailable), the processes deadlocked after only a few data flow actions. The problem was traced to a mistake in the generated HEP self-scheduling code associated with wake-up barriers for processes with more than one output datapath. The error involved the omission of an LAREAD for asynchronous variables during process wakeup. (The code for HEP-OS was correct, the translation for UPX was in error). The fix was a change to part of one line in the LGDF macros, and took about five minutes. The error was difficult to diagnose, and was found during a visit to Los Alamos using the sgsdb debugging facility[7].

An example of an erroneous LGDF process execution barrier that was produced is:

```
CALL AWRITE ($DW(5),GO)
CALL AWRITE {$DW(6),$DW(5)}
CALL AWRITE {$DW(7),$DW(6)}
GO=LAREAD ($DW(7))
```

which should be:

```
CALL AWRITE ($DW(5),GO)
CALL AWRITE {$DW(6),LAREAD ($DW(5)) }
CALL AWRITE {$DW(7),LAREAD ($DW(6)) }
GO=LAREAD ($DW(7))
```

[lgdf-p10.f 26 to 29]

- 4) Another change was needed because the version of HEP/UPX we used does not automatically interlock parallel attempts at I/O. No error indication is given, the I/O just behaved erratically. As an example, the prompt for user input written to Unit 6 (stdout) would occasionally show up on the terminal, but most often would appear in the trace file (opened as Unit 4)! The macros lockio\_ and unlockio\_ were added to provide a way for users to do mutual exclusion of I/O between user processes and all other I/O (including trace file writes) in a transparent way. Examples can be seen in p14 at [lgdf-p14.m 13 and 105].

GAMTEB was then run successfully in parallel LGDF mode with 12 parallel processes (including six clones of p17) and produced correct results.

When we attempted to run timing tests with 30 clones of p17, a strange HEP/UPX system error occurred which is still being investigated at this writing. When the problem is resolved, timing curves will be submitted as an added appendix to this report.

Roadblocks to progress:

- 1) The HEP at LANL was often unavailable during the period of this contract. On several occasions it was down for a week or more (for example, when the new operating system was installed). On another occasion, the HEP appeared to be down when it was not, due to a change in login procedure that we were not aware of.
- 2) During those times, we attempted to proceed with work on GAM-TEB by using the HEP at Argonne. Unfortunately, the Argonne HEP down-time seemed frequently to overlap with that of the LANL HEP. (One reason for this is that the Argonne HEP also installed HEP/UPX during this time period).
- 3) We frequently had difficulties with remote logins at both Argonne and LANL. This often took a dozen or more tries. It was sometimes rather frustrating to then discover that the HEP was down!
- 4) On both HEP's, we encountered several serious problems:
  - a) Compilation was sometimes random. A source file might produce error messages during several attempts to compile it, then compile successfully (unchanged) at a later time.

- b) A problem with the linker made it difficult to get an executable version. This was eventually fixed.
- c) The current problem with the disk (described elsewhere) prevents running the benchmarks.

## 7. CONCLUSIONS AND RECOMMENDATIONS FOR FURTHER WORK

The portability problems (discussed in Section 3), we encountered with getting the original (non-LGDF) GAMTEB running on the VAX (sequentially!) were much more difficult and time-consuming than any of the problems encountered in either creation of the LGDF model version, or in fixing the problems with the generated parallel self-scheduler on the HEP. This was something of a surprise, since we expected the opposite to be the case.

Based on the experiences related in Section 4, if Large-Grain Data Flow techniques are to be applied practically in converting existing large-scale scientific application codes for parallelism, a "smart data flow editor" would be necessary to avoid making the kinds of minor "bookkeeping errors" we encountered.

### Future Work

Specific future tasks contemplated related to this work include:

- 1) Complete speedup experiments for the parallel LGDF version of GAMTEB.

- 2) Add graphic tracing specifications to the GAMTEB "wirelist" file for graphic execution monitoring.
- 3) Develop a graphics editor for entering LGDF network diagrams (to run on a variety of inexpensive graphics terminals--initially on IBM PC and Tektronix 4105 class intelligent graphics terminals).
- 4) Investigate techniques for "non-intrusive" LGDF parallel process execution monitoring. The aim is to provide rapid, real-time visual feedback on run-time characteristics for various parallel algorithms in such a way that the monitoring does not significantly distort the run-time characteristics compared to an unmonitored LGDF program. [\*]
- 5) Develop an LGDF scheduler for CRAY X-MP class parallel processors. This would involve both multi-tasking using the CRAY Multi-tasking Library and "micro-tasking" by generating specialized CRAY assembly language (CAL) scheduling instructions.
- 6) Develop an LGDF scheduler for "hypercube" architectures without shared memory, such as the Intel iPSC.

### Conclusions

During the period of this research work, the HEP underwent a major change in operating system as pre-release versions of the

---

[\*] A videotape, "The Traffic Light Demo", showing an example of a color graphic execution monitoring facility for an LGDF program, is available from the authors of this report.

HEP Unix Parallel Executive (UPX) gradually replaced the earlier HEP-OS system. Because of the transparent parallel operation made possible by the LGDF approach (i.e., users do not code any explicit parallel calls or synchronization statements), this shift was accommodated relatively easily and caused only minor problems.

We see the problem of lack of portability of parallel scientific application codes as becoming a major problem, particularly for the National Laboratories. The techniques described in this report show promise for providing a solution to this problem.

The long-term goal of our work with Large-Grain Data Flow is the development of a scientific programming environment that will help bridge the gap between the current sequential FORTRAN environment and both current and future parallel processor supercomputers.

### **1. INTRODUCTION**

Programming parallel processors can be very frustrating. In addition to the usual software engineering problems common to all forms of program development, an additional set of problems must be avoided and additional criteria must be met for a parallel program to be judged successful. Software engineering problems directly related to the introduction of parallelism include:

- Deadlock and livelock avoidance
- Preventing race conditions
- Avoiding creation of too many parallel processes
- Detecting program termination

New evaluation criteria for parallel programs include:

- Program speedup versus number of processors
- Size of synchronization overhead
- Effect of problem size on speedup
- Max. number of processors that can be kept busy
- Is the program deterministic?

In addition, new software design issues arise, such as:

- What size program "chunks" should be used?
- How many parallel processes should be created?
- What form of process synchronization should be adopted?
- How should access to shared data be managed?
- How can deterministic program execution be guaranteed?

---

† This work was supported in part by Denelcor, Inc., Aurora, Colorado, under Contract 84-S-010, and Los Alamos National Laboratory under Contract 9-Z-34-P-3915-1.

- How should processing tasks be sub-divided to make the most effective use of available parallel hardware?

Debugging parallel programs is notoriously difficult. Race conditions can masquerade as program logic errors. When deadlock occurs on the HEP, for example, the addresses where the various parallel processes are "hung" can be determined. However, figuring out how the program got *into* the deadlock situation is usually much more difficult. Debug tracing can affect the parallel behavior of the program being debugged. Non-deterministic programs sometimes "fix themselves" when debug tracing is added, since the tracing serializes a portion of the execution.

The Large-Grain Data Flow (LGDF) methods described in this chapter represent an attempt to provide an abstract computational model for parallel processing that is easy to understand, yet powerful enough to address the questions and issues listed above. Another goal of the methods is to provide a model that can be implemented on a wide variety of *both* parallel and sequential architectures. In this paper the discussion and all of the examples refer to HEP-OS Fortran77[1] for the Denelcor HEP-1 parallel processor[2].

The next section presents an introduction to the LGDF computational model, notation, and semantics. Section 3 presents an overview of the steps involved in using the LGDF Macro Toolset to implement parallel programs. In Section 4 the solution to a small numerical programming example is presented—the parallel solution of a triangular system. Conclusions and references to related work can be found in Section 5.

## 2. LARGE-GRAIN DATA FLOW

Considerable research effort during the past 15 years has been devoted to the study of dataflow machine architectures and languages as a means to achieve highly parallel computation[3]. The source of parallelism in the data flow approach arises from the possibility of simultaneous execution of a large number of independent operations whose operands have been previously computed. Operations are conceptually linked in a network so that the result of each local computation is fed automatically into the appropriate inputs of other operations. Although traditional dataflow approaches provide an attractive basis for parallel processing, only a few experimental dataflow machines have actually been built[4] [5] and data flow languages such as ID[6], VAL[7], SISAL[8] and LAU[9] have not been widely accepted.

A major parameter in parallel processing is the size of the "granule" of computation that is executed in parallel. In traditional programs for Von Neumann computers, a granule corresponds to an entire application program, and little parallelism within an application program can be exploited. On the other hand, in most dataflow work to date, the grain size chosen for parallel scheduling has been at

the level of a single arithmetic or logical operator. Large-Grain Data Flow combines features of both approaches. The large grain structure of application programs is represented explicitly.

The LGDF computation model resembles traditional data flow in that LGDF processes are activated and controlled by the arrival of and consumption of data values. An *LGDF process* can be in one of three process-states: *executing*, *suspended*, or *terminated*. While executing, in addition to arithmetic and logical computation on input data values it can also perform data flow control actions corresponding to:

- the consumption of data values
- the production of data values
- changing the case-state of process
- reiteration of a process
- suspension of a process

All processes are initially suspended. Processes are represented diagrammatically by circles as shown in Fig. 1. Each process is given an associated descriptive name, and a unique p# tag. An *LGDF data path* is a data memory shared among a number of LGDF processes. Data paths are represented by several types of directed arcs, as shown in Fig. 2. Each data path is also given a descriptive name, and has associated a unique d#. In addition to data values, each data path has a data-state: *empty* or *full*. All data paths are initially empty. Processes and data paths are linked together into acyclic networks of producers and consumers of data as shown in Fig. 3. LGDF networks can achieve parallel operation based on simple producer/consumer data flow interactions. Processes are activated asynchronously depending only upon the empty/full data-states of their associated input and output data paths. All LGDF processes must obey the following two rules:

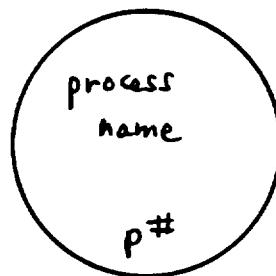

Fig. 1. Graphic representation of an LGDF process.

(a) Clearable data path.

(b) Non-clearable data path.

(c) Side-effect (non-controlling) data path.

Fig. 2. Graphic representation of LGDF data paths.

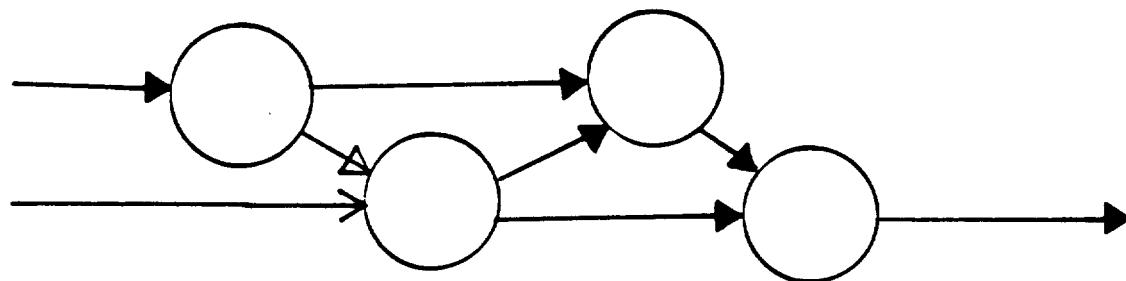

Fig. 3. Graphic representation of an LGDF process network.

**Execution Rule.** An LGDF process may change its process-state from suspended to executing only after all of its associated input data paths are full, and all of its output data paths are empty.

**Data Flow Progress Rule.** Upon suspension of an execution cycle, an LGDF process is required to have made data flow progress. This means that it has cleared (consumed) at least one input, or it has set (produced) at least one output during the current execution cycle. Otherwise, the process is terminated.

Setting an output data path has the effect of making the data path available to activate downstream processes. In a similar fashion, processes that clear their input data paths can indirectly activate upstream processes by making a data path available for writing. During any one execution cycle for a process, each of its input data paths can be cleared at most once. Similarly, each of its output data path can be set at most once. Processes are allowed to read data values

only from full input data paths and write data values only on empty output data paths.

Processes can have two types of access to values on input data paths:

- *Read-only*—associated data values may be referenced, but not changed.
- *Update*—associated data values may be both read and changed.

Input data paths that are of type update correspond to variables in ordinary programming languages. Read-only data paths correspond, for example, to constants or call-by-value function arguments. Graphic notations for read-only and update data paths are shown in Fig. 4. LGDF processes are restricted to write access to their output data paths.

Access to data values, for example, arrays, can be shared among a set of LGDF processes in two different ways:

- sequential shared access
- parallel shared access

A sequentially shared data path represents a data memory which is controlled so that at most one process has access to the shared data values at a time. This corresponds to forcing serialization of that portion of the computation. A parallel shared data path represents a data memory in which asynchronous access is possible by a set of processes. Processes that access a parallel shared data path can also compete non-deterministically for exclusive access to the shared input or output. Notations for sequential and parallel shared data paths, for both read-only and update access, are shown in Fig. 5.

LGDF process networks can also be defined hierarchically. This means that any node in a network may be specified either by an LGDF process (as discussed above) or by another network. The semantics of this are the same as if all references to lower level networks were replaced by their defining networks. This

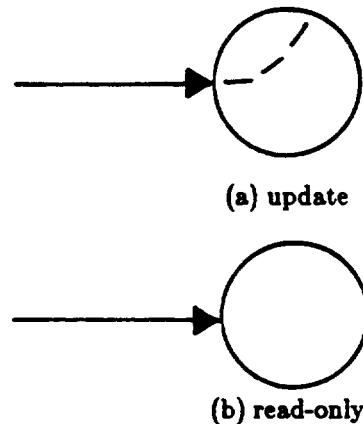

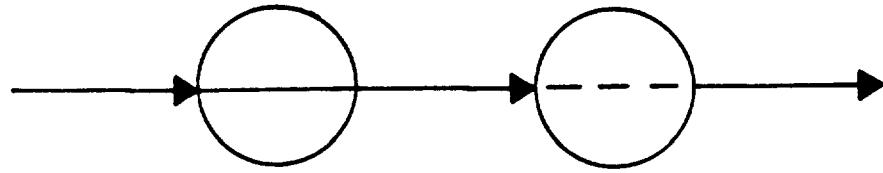

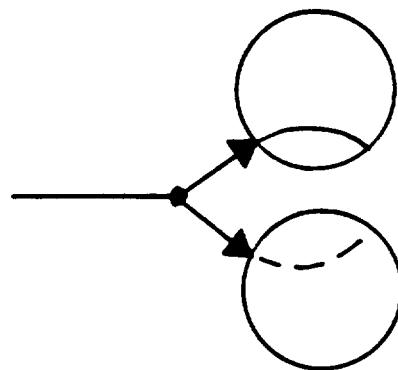

Fig. 4. Graphic representations for update and read-only data paths.

Fig. 5. Graphic notations for shared data paths.

grouping mechanism is used to cluster processes that execute with approximately the same frequency<sup>1</sup>.

LGDF application designs tend to deal with data-activated chunks that correspond typically to 5 to 50 lines of executable higher-level language statements. This has the effect of providing a relatively familiar subroutine-like interface for programmers, as shown in Fig. 6.

LGDF network diagrams specify unambiguously which SUBROUTINE parameters are inputs (X), which are outputs (Y,J), and which are both (I). Another difference is that a programmer does not CALL a SUBROUTINE for execution, but activates it indirectly by sending data to it.

---

<sup>1</sup>On a single PEM HEP, the process grouping information is not used directly, since all processes are effectively at the same scheduling level (a 128-way single-level parallel process scheduler is built in to the hardware). However, when emulating LGDF parallel operation on a sequential computer, the round-robin scheduling mechanism can be made more efficient, because processes that execute infrequently are checked less often for executability.

### 3. USING LGDF MACROS FOR PARALLEL PROGRAMMING

In this section, we give an overview of the steps involved in implementing a parallel Fortran program on the HEP using the Large-Grain Data Flow Macro Toolset. The steps involved in using the LGDF macro tools are:

- 1) *Draw LGDF Network Diagrams*—The goal in designing an LGDF process network to solve a problem is to produce a hierarchical, consistent<sup>2</sup> set of network data flow graphs that embody the large grain logical data dependencies inherent in the problem.

Parallelism can be achieved in several ways. The simplest kind of parallelism in the LGDF computation model is *data-independent* parallel processing. Any two executable LGDF processes that share no data paths can safely execute simultaneously since they cannot interfere with each other.

The next simplest method is *data-sequential* or *pipelined* parallelism. In a pipeline, a series of processes can be active simultaneously on different phases of the production of a final result. This is the same idea exploited in the floating point units of vector processor supercomputers and in UNIX<sup>3</sup> pipes[10].

The third method is *asynchronous-parallel-update*. This is “risky” parallel processing, where multiple processes have asynchronous read and/or update access to a shared data structure (usually an array). It is the LGDF programmer’s responsibility to ensure that the updates are performed safely and correctly. A common way to ensure this safety is to prevent two processes from trying to update the same array element at the

<sup>2</sup>A set of data flow graphs is consistent if the inputs and outputs of each LGDF system process match the input and output data paths shown on the corresponding lower level defining network.

<sup>3</sup>UNIX is a trademark of Bell Laboratories.

same time.

The Triangular Solver example contains examples of all three types of parallelism.

- 2) *Create Wirelist File*—The Wirelist file uses macros to declare names and internal tags for processes and data paths. The data flow dependencies of the set of data flow diagrams from step 1) are also encoded using macro calls<sup>4</sup>. The macros indicate which data paths are inputs and which are outputs for each process and process network. Also encoded are the type of access each process has to its input data paths: clearable (CL) or non-clearable (NC), and read-only (RO) or update (UP).
- 3) *Package Data Declarations*—Fortran data declarations corresponding to each data path in the data flow diagrams are put into separate files whose names correspond to their data path tags. (These become labeled COMMON declarations in the generated programs).
- 4) *Write LGDF Programs*—Combine LGDF macro calls with appropriate Fortran code to implement each program. The LGDF programmer writes macros for execution barriers and actions. Data flow control macros are used to signal consumption of inputs and production of output values. Other macros are used to change the case-state of a process, and to reiterate, or suspend execution.
- 5) *Macro Expand LGDF Programs*—The wirelist and data declaration files are used to control the macro-expansion of the LGDF program files to produce compilable Fortran for a particular machine. The expansion is based on the data path connectivity information encoded in the Wirelist File. SUBROUTINE headers and labeled COMMON statements corresponding to a program's input and output data paths are inserted automatically.
- 6) *Compile and Execute*—The resulting source code is then compiled including, if desired, pre- and/or post-compilation optimization steps available for the particular target environment.

See [11] and [12] for further details on LGDF methods for software engineering and parallel processing.

---

<sup>4</sup>This step is currently done manually, but will eventually be an automatic result of a graphics-based tool used to draw LGDF network diagrams.

#### 4. SOLVING A TRIANGULAR SYSTEM

Presented below is a detailed example of LGDF programming for the HEP. The development of the example assumes familiarity with the terms and notation defined in Section 2. All user-coded inputs to the macro expansion process are shown, as well as samples of the expanded Fortran code.

The problem is to solve a lower triangular matrix  $T$  (of dimension  $N$  by  $N$ ) to yield a result vector  $Y$  (of dimension  $N$ ). The parallel solution strategy employed is to break  $T$  up into sub-matrices of dimension (usually)  $K$  by  $K$ . Since  $K$  may not evenly divide  $N$ , we will in general have a column block of submatrices left over that will be less than  $K$  columns wide. We choose to put this narrow column of submatrices at the left edge of  $T$ , as shown in Fig. 7 for the case  $N=8$ ,  $K=3$ .

Again, referring to Fig. 7., the basic approach is employ a triangle solver (TS) to update  $Y$  for the first triangular group of  $T$  values labeled  $TS_1$ . After this TS process has finished updating the result vector  $Y$ , a series of matrix multiply (MM) processes can begin execution in parallel for the column block below. Each of the matrix multiply steps is independent. However, care must be taken that parallel updates to the result vector  $Y$  by the various MM's are performed safely.

The next triangle solver step on the diagonal ( $TS_2$ ) must wait until all of the matrix multiply steps in the same row block to its left have completed their updates of  $Y$ . Then a series of matrix multiply processes can be started in the column block below, and the pattern repeats. The LGDF solution to this problem employs an "interlock" data path to block the next triangle solver step until

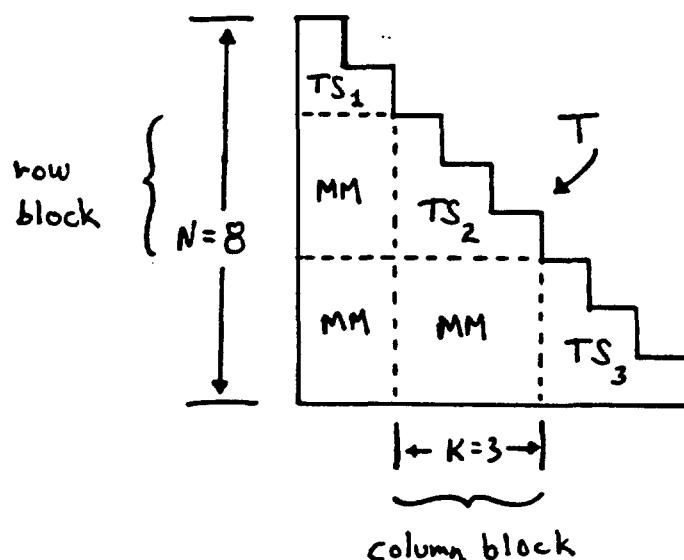

Fig. 7. Solution strategy for the parallel triangular solver.

the appropriate matrix multiply steps have completed. The interlock is cleared by use of a matrix multiply "check-in" process (MMCKIN) that counts the number of matrix multiplies that have completed in each row block. When the row block of MM's has finished, a row block completion signal is produced that causes the triangle solver interlock data path to be cleared.

In the discussion of the LGDF solution below, p and d numbers are used to cross-reference the various networks, processes, and data paths with program texts.

#### **4.1. Draw LGDF Network Diagrams**

The LGDF solution to the parallel triangular matrix solver is shown on three process network diagrams, in Figs. 8-10. The top level network (p00), shown in Fig. 8, consists of a process TSINIT (p10) that sets up a problem to be solved (d01), initializes the result vector Y (d02) to zeros, and initializes various counters and index values (d03, d04). TSINIT can execute immediately because all internal data paths in a network hierarchy are initially empty. The system<sup>5</sup> TMWORK (p01) then updates the result vector Y in place to produce the final result vector (d02a)<sup>6</sup>. The dashed lines inside the circle for p01 for data paths d03 and d04 indicate that their contents can be updated by processes running inside p01. Note that data path d01 can be cleared by processes internal to p01, but the associated TS problem values can not be changed.

An LGDF process network definition of TMWORK (p01) is shown in Fig. 9. The notation in square brackets "[p00]" below p01 on Fig. 9 indicates the parent (context) network process for a network. The program TSWORK (p11) controls all of the remaining processes in the solution, either directly or indirectly. Since it "knows" the global state of computational progress, it can produce the answer by setting the result vector Y (d02a) after all final Y values have been computed. TSWORK causes a triangle to be solved by TS (p12) by setting appropriate TS control values on d04a. It then blocks itself from further execution until the appropriate matrix multiplies have completed inside MMWORK (p02) by setting the next row block interlock NRBI (d05). NRBI is cleared by WAITRB (p13) after the next row block complete signal NRBC (d07) is produced inside p02. After TS has updated Y (d02), it starts the matrix multiplies below it by setting appropriate MM control parameters (d06). Note that both p12 and the processes inside p02 have asynchronous update access to Y (d02), a potentially unsafe situation.

---

<sup>5</sup>We use the term "system" for processes that are defined by a network, rather than by an LGDF program.

<sup>6</sup>Note that even though d02 and d02a represent the same array, they are assigned different data path tags, and can be independently set and cleared. The open arrowhead on data path d02 indicates that no process inside p01 is allowed to explicitly clear the result vector. (It is said to be *non-clearable*). However, a mechanism is provided in the generated Fortran code to automatically propagate a "clear" backwards for shared data paths when the corresponding shared output is cleared, which in this case would have to be done by a process external to this network.

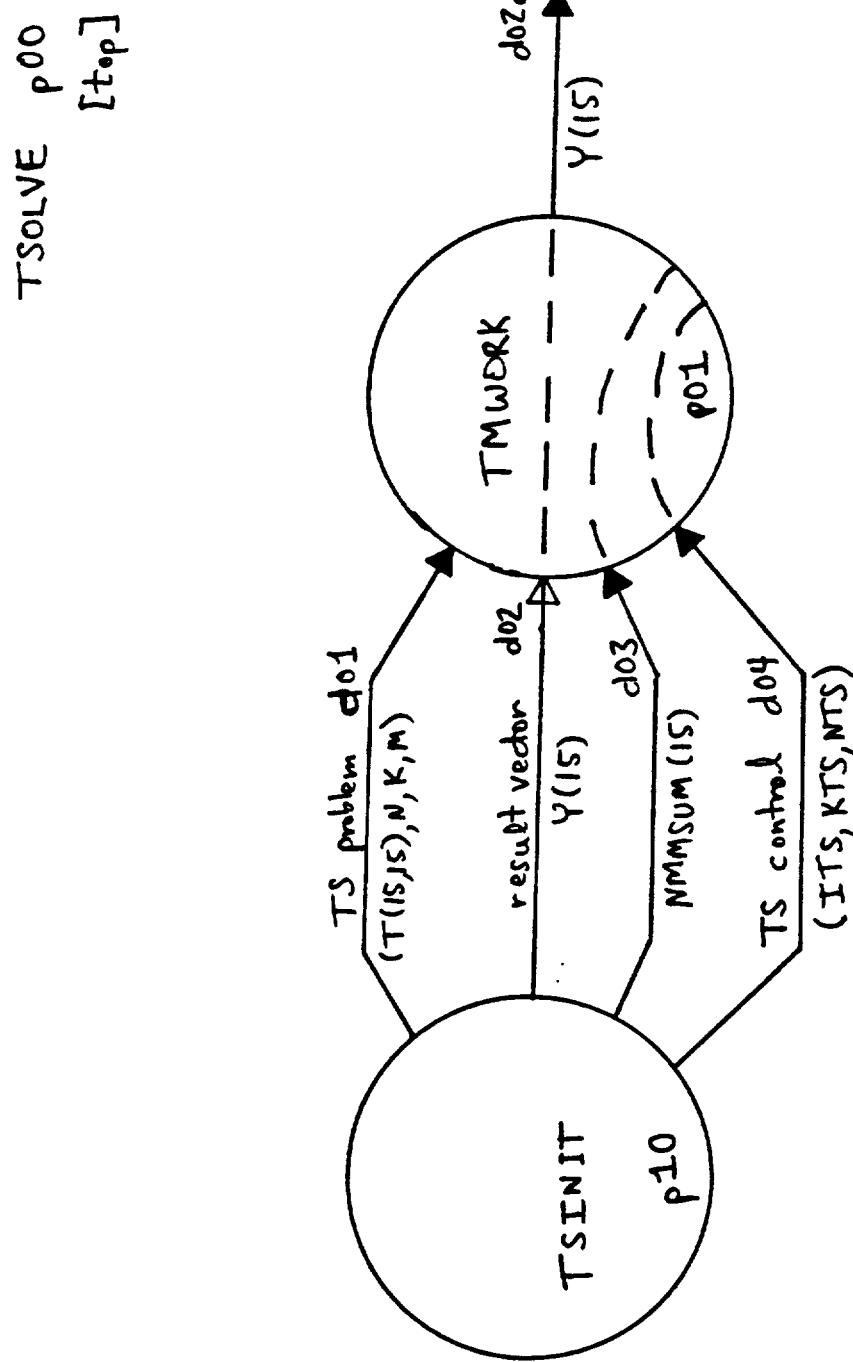

Fig. 8. LGDF process network for  $\text{TSOLVE } (p00)$ .

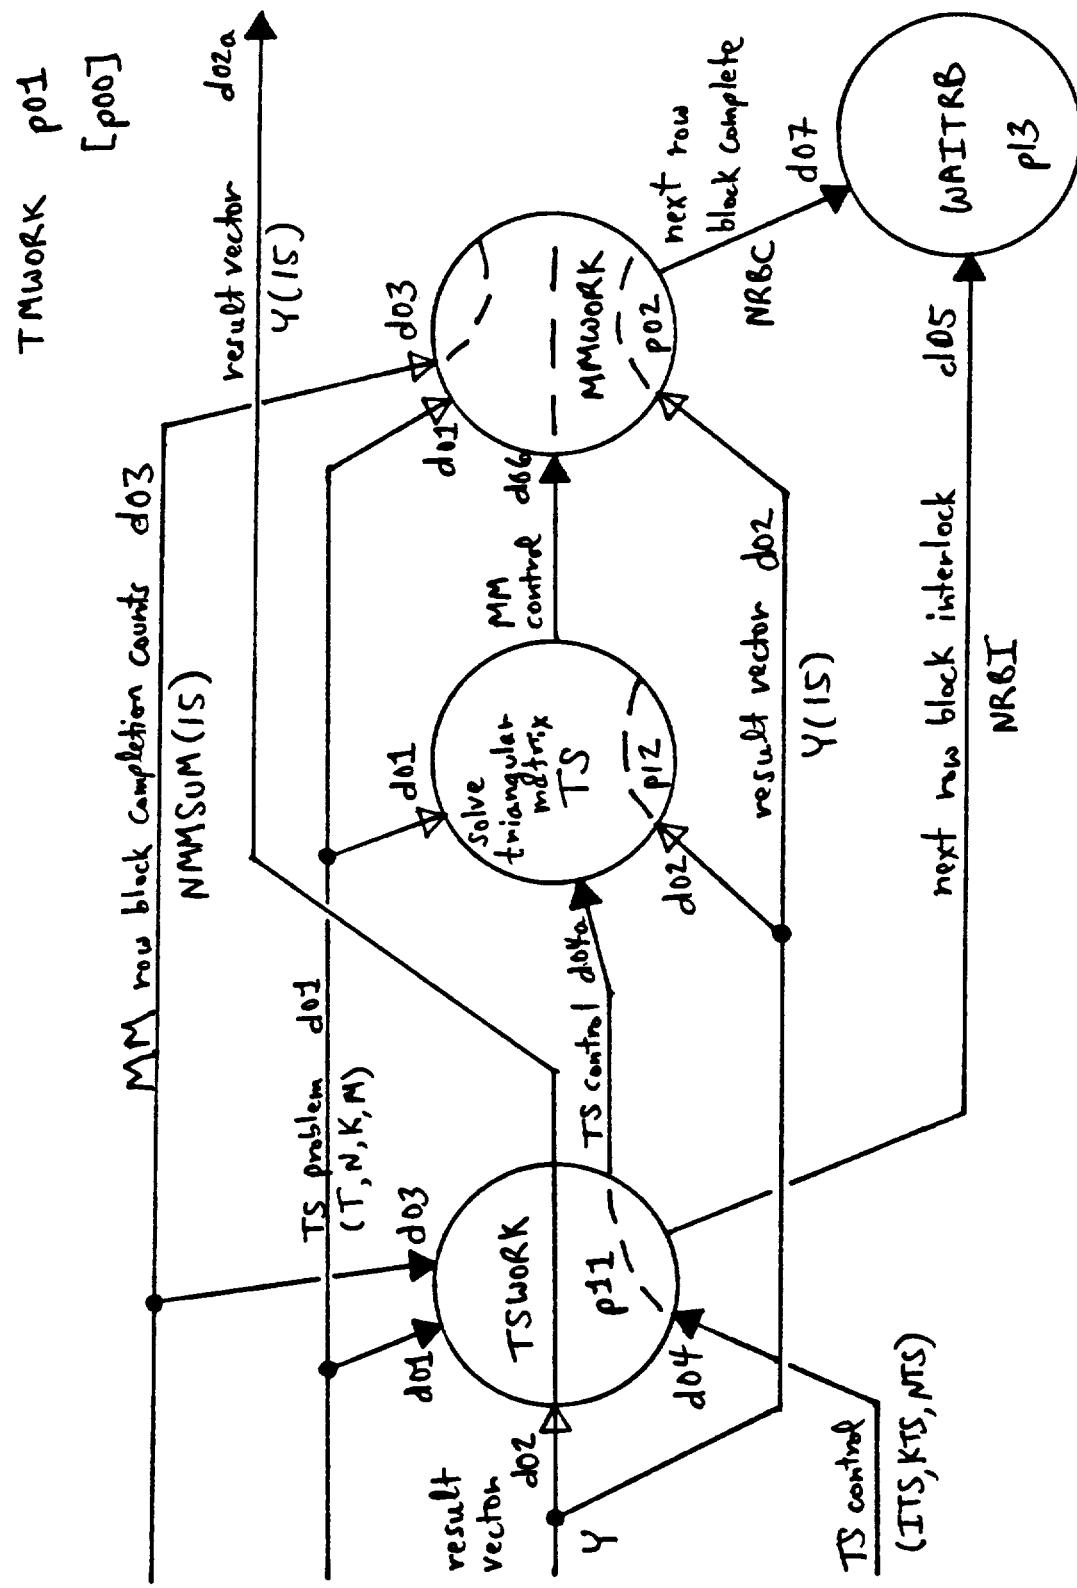

Fig. 9. LGDF process network for TMWORK (p01).

The lowest level LGDF process network for this example is for MMWORK (p02), shown in Fig. 10. MMWORK (p14) generates the next MM sub-problem (d06a). A collection of MM processes (p15) compete asynchronously for work on d06a. After an MM process gets exclusive read access to d06a, it makes local copies of the MM control values and clears d06a, allowing p14 to generate the next MM sub-problem immediately. Each MM computes its contribution to the result vector Y using an array local to each copy of p15. When it has completed its computation, it competes for exclusive write access to the MM checkin data path (d08). Since only one MM process can be checking in at a time, it can also safely update Y during this time. MMCKIN (p16) counts the number of MM processes that have completed by row, and when all have checked in, sets the next row block completion signal NRBC (d07).

#### **4.2. Create Wirelist File**

A *Wirelist File* is a set of macro calls consisting of two parts. The first part, shown in Fig. 11, defines data path and program names and tags. The tags are then used in the second part, which consists of a series of macro calls that encode the connectivity, and data path and process types of a set of LGDF process network diagrams. The wirelist corresponding to the diagrams in Figs. 8-10 are shown in Fig. 12. Error checking is incorporated in the macro expansion process. Errors diagnosed include use of an undefined d or p tag and input of a data path that is neither an external input, nor the output of another LGDF program. Data path type errors are also diagnosed, such as inconsistent usage of clearable and non-clearable data paths.

#### **4.3. Package Data Declarations**

Data declarations corresponding to data paths are retrieved from separate files. The data declaration files for this example are shown in Fig. 13.

#### **4.4. Write LGDF Programs**

The complete LGDF macro forms for programs p10 through p16 are shown in Fig. 14.

#### **4.5. Macro Expand LGDF Programs**

A sample program (p12) macro-expanded for the HEP is shown in Fig. 15. Also generated is a top-level initiation program and a set of network initiator subroutines, one for each network diagram. The top-level initiation program that contains trace aid facilities and code which prints out run statistics and the final set of data path states. It also calls the top-level network initiator subroutine (in this case p00) which creates the other LGDF processes in the network. Each process can be created only once in the current version of the tools. Network initiator subroutines for TSOLVE (p00), TMWORK (p01), and MMWORK (p02) are shown in Fig. 16.

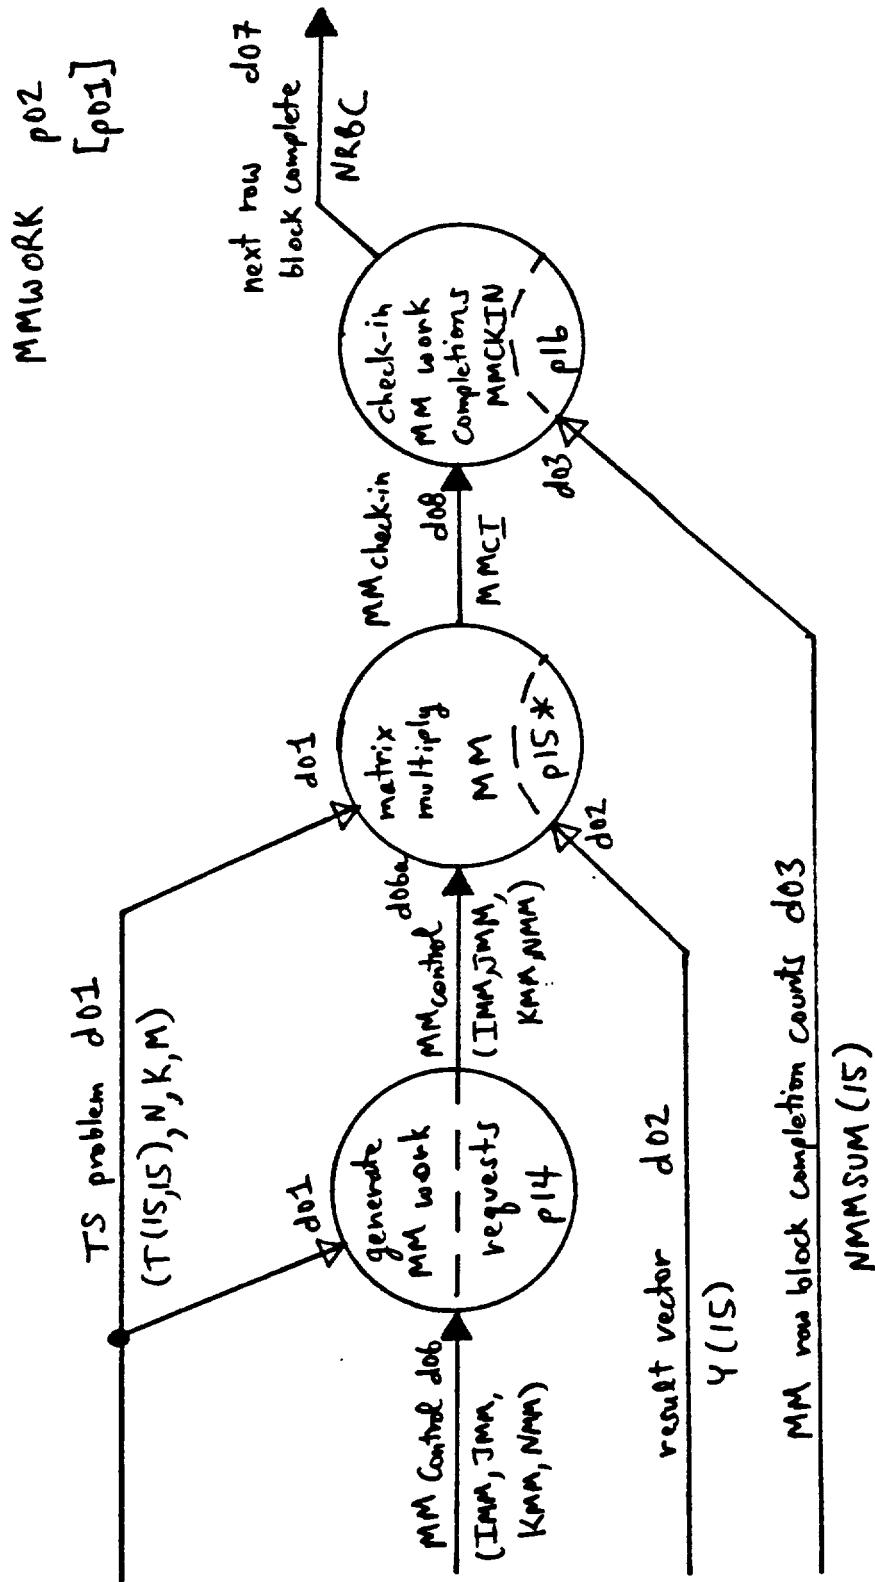

Fig. 10. LGDF process network for MMWORK (p02).

Fig. 16. Network initiator subroutines for the parallel triangular solver example.

#### **4.6. Compile and Execute**

The output of the macro-expansion step is compilable Fortran for the particular target machine. The code can be further pre-processed in environments where Fortran pre-processing tools such as vectorizers are available. Of course, the object code can be further optimized automatically also.

### **5. CONCLUSION**

The basic asynchronous variable mechanism available on the HEP appears deceptively simple. This apparent simplicity can lead even very good programmers, with a good understanding of parallel processing and of the HEP architecture, into very deep asynchronous-parallel update trouble. Several other researchers[13] [14] [15] have concluded that a good way to avoid some of the pitfalls of bare-knuckled parallel processing on the HEP is to program using a relatively simple set of macros to express barriers and other synchronization abstractions. The macros are then expanded into appropriate primitive synchronization actions. Despite the fact that the parallel abstractions supported by the various macro packages are quite different, most people who have tried any of them have found parallel programming much easier. This would appear to be a time to experiment with various abstractions, and to gain experience with software engineering methods to aid in parallel programming. Eventually, the more successful of these abstractions could be encapsulated in later versions of Fortran and other scientific programming languages.

We have come to some unexpected conclusions as a result of our work in modeling algorithms using "safe" parallel (data-independent), pipelined (data-sequenced), and "risky" parallel (asynchronous shared update) LGDF network data flow patterns. The most surprising is that "sequential" programs are often easier to design and implement reliably when based on a parallel (asynchronous) model of computation. The extra difficulty of the traditional implementation approach arises because of the artificial sequencing imposed by conventional programming.

Using the prototype toolset based on macro expansion techniques, we have demonstrated that the same "macro" program can be run efficiently (unchanged) on a sequential and a parallel processor. The program ran with simulated parallelism on the sequential processor (a VAX) and with real parallelism on the parallel processor (a HEP-1). It is hoped that the software engineering methods described in this section will form the basis for programming a wide variety of parallel architectures.

## 6. Acknowledgment

The ideas in this paper have been developed over a period of several years, and many people have contributed to their current form. The author would like to acknowledge especially the contributions of James Hardy, Robert Hiromoto, Richard Kieburtz, Richard Hamlet and Danny Sorensen. Dr. Sorensen suggested the Parallel Triangle Solver problem and solution approach, and helped develop both the LGDF process network diagrams and the LGDF programs.

**APPENDIX C**

**[f77]**

**FORTRAN77 Sequential GAMTEB**

KEY TO ANNOTATIONS:

PROGRAMS

p00: Scalar Monte Carlo Transport Code  
p10: set up problem constants  
p12: initialize run parameters  
p13: set up for particle counting  
p14: format and print report  
p16: generate random seed for next particle  
p17: run history for one particle and offspring  
p18: check for run completion

DATA PATHS

d03: problem constants  
d04: converted cross-section tables  
d06: run statistics  
d13: first random number seed

CHANGES

OLD: original code  
NEW: miscellaneous changes needed for the VAX  
ALG CH: Monte Carlo random number generator installed  
BUGFIX: REAL/INTEGER equivalence replaced by INTEGER/INTEGER  
and REAL/REAL equivalences, KRN put in COMMON  
RENAME: variable names reduced to 6 characters  
EXTRA: removed extra initialization  
STYLE: REAL initialized with REAL value

## APPENDIX D

[lgdf]

### LGDF Parallel GAMTEB

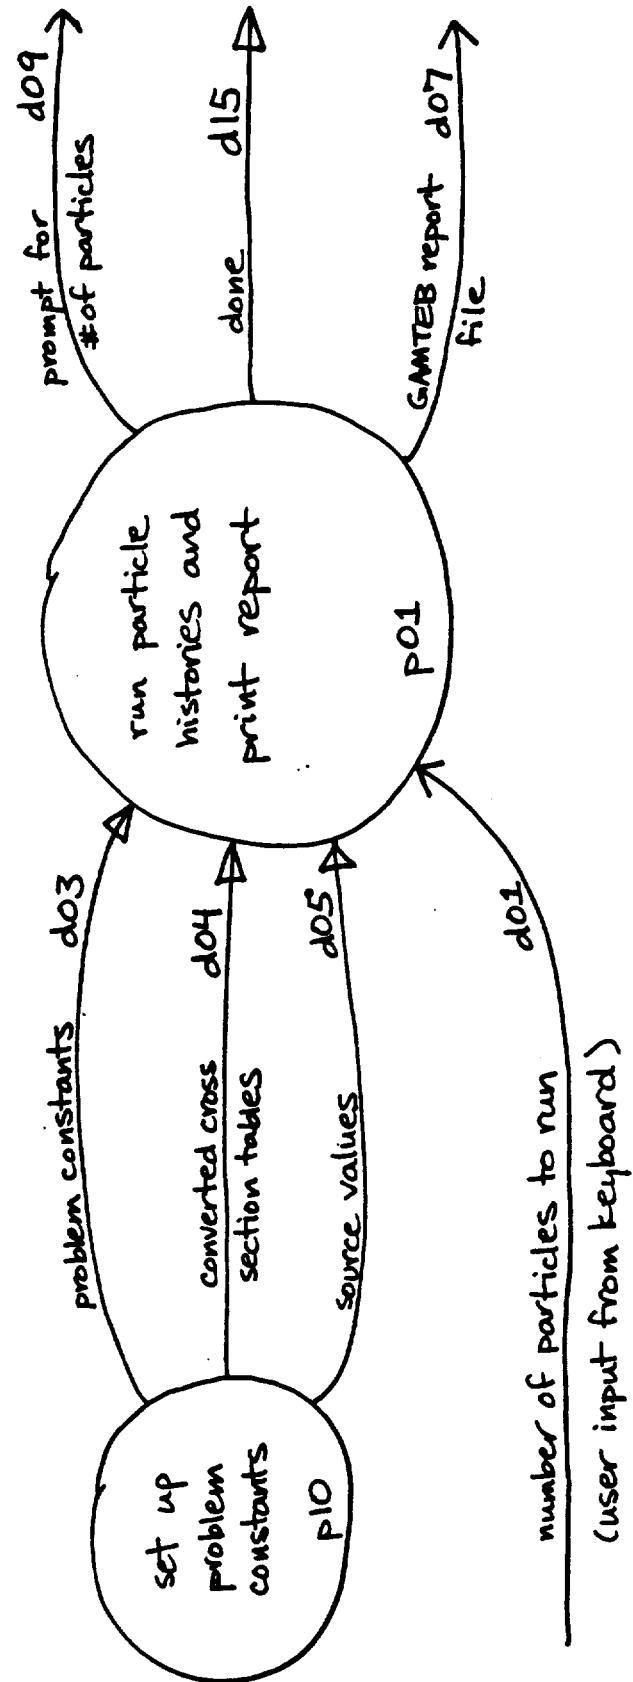

1. Project File - used to control the macro expansion process
2. LGDF Network Diagrams - express data-process dependencies
3. Wirelist - machine-readable form of LGDF network diagrams
4. Data Dictionary - description of data items associated with each data path
5. Data Declarations - FORTRAN fragments used to construct labeled COMMONs
6. Process Definitions - LGDF macro form

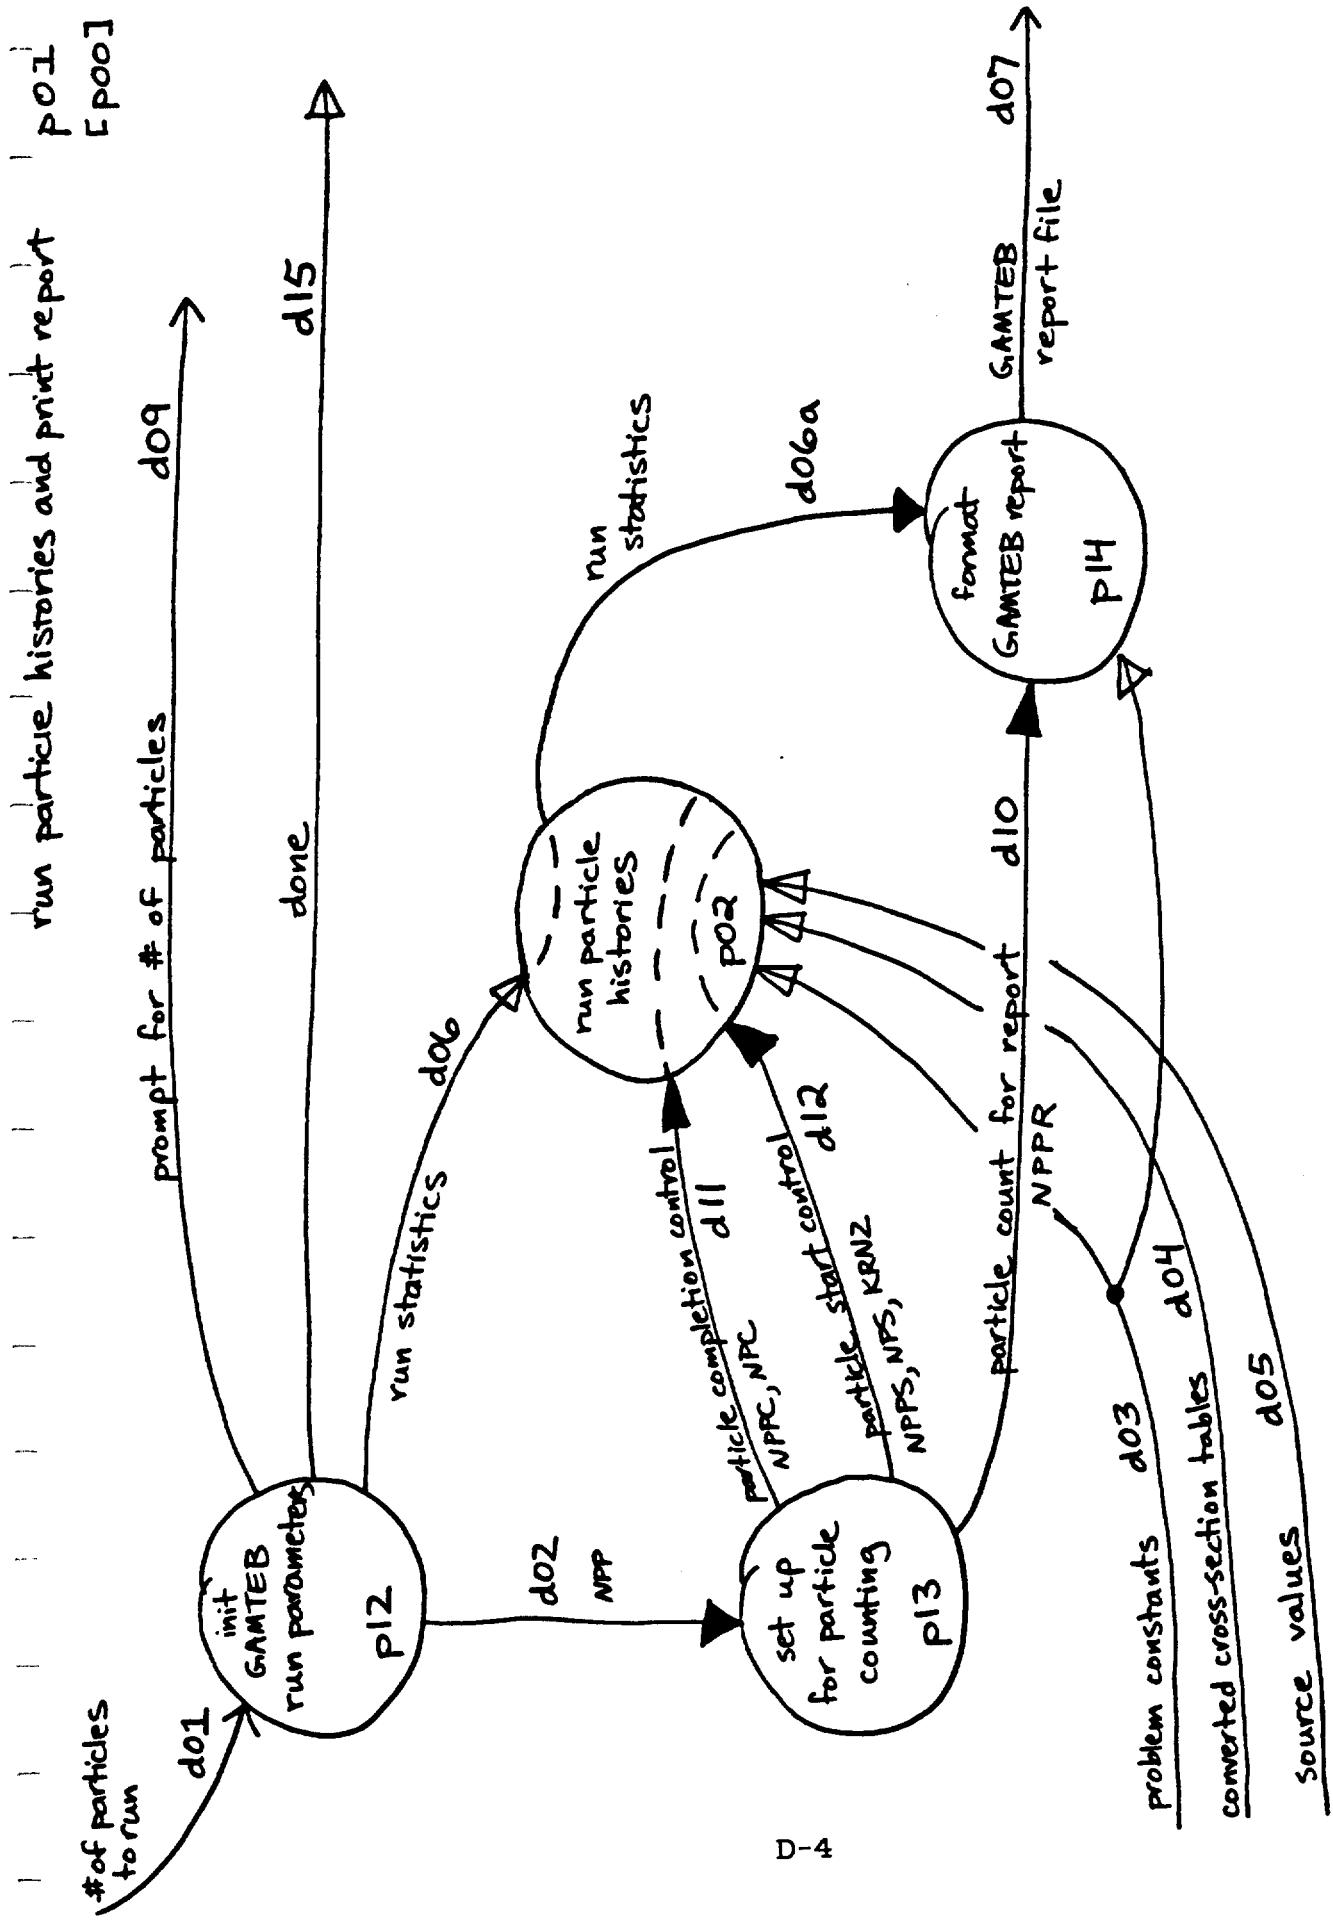

Apr 17 14:01 1985 Project Page 1

May 1 10:49 1985 DD Page 1

d01

ID01 - number of particles to run (input from user)

d02

NPP - number of particles

d03 - problem constants

E(35) - energy constant table

RHO - constant

CL - cylinder length

CL2 - cylinder length + 10

CRAD - cylinder radius

CRAD2 - cylinder radius squared (CRD2)

WCP1 - weight cutoff 1

WCP2 - weight cutoff 2

EC - energy cutoff

FIM(2) - flip

d04 - converted cross section tables

EL(35) - log of energy constant table

XC(35)

XPP(35)

XPE(35)

d05 - source values

GIERG - energy

GIWT - mass

GIU - direction

GIV "

GIW "

GIX - position

GIY "

GIZ "

IGIA

d06 - run statistics

IGNCOL - number of collisions

IGNCO - tracks lost to weight cutoff

GWCO - weight lost to weight cutoff

GWCP - weight created by weight cutoff

GWRL - weight lost in russian roulette

IGNR - tracks lost to roulette

WRG - weight created by roulette

IGCUTF - no. of particles cut off when energy .LE. EC:d4b

GABSOR - weight absorbed

IGNS - no. of tracks created by splitting

GTRANS(35) - transmitted weight total by energy level

GESCAP(35) - escaped weight total by energy level

GBSCAT(35) - back-scattered weight total by energy level

GTRNS2(35) - sum of squares of GTRANS

GESCP2(35) - sum of squares of GESCAP

GBSCT2(35) - sum of squares of GBSCAT

GTRNSI(35) -

GBSCTI(35) -

GESCPI(35) -

GBTOTI - back-scattered weight total

May 1 10:49 1985 DD Page 2

GETOTI - escaped weight total  
GTTOTI - transmitted weight total  
GBTOT2 - sum of squares of BTOTI  
GTTOT2 - sum of squares of TTOTI  
GETOT2 - sum of squares of ETOTI

d07  
gamteb report

d08  
[not assigned]

d09  
prompt for # of particles

d10  
NPPR - particle count for report

d11 - particle completion control  
NPPC - no. of particle history summary statistics (d14) expected  
      (= NPP (d02))  
NPC - particle history completion counter

d12 - particle start control  
NPPS - no. of particles to start  
      (= NPP (d02))  
NPS - particle history start counter  
KRN2 - second random number seed

d13  
KERN - first random number seed (\$KRN)

d14  
NCOL - number of collisions  
NCO - tracks lost to weight cutoff  
WCO - weight lost to weight cutoff  
WCP - weight created by weight cutoff  
WRL - weight lost in russian roulette  
NR - tracks lost to roulette  
WRG - weight created by roulette  
NPS - particle counter  
CUTOFF - no. of particles cut off when energy .LE. EC:d4b  
ABSORB - weight absorbed  
NS - no. of tracks created by splitting  
TRANS -  
ESCAPE -  
BSCAT -  
TRANS2 -  
ESCAP2 -  
BSCAT2 -  
TRANSI -  
BSCATI -  
ESCAPI -  
BTOTI - back-scattered weight total  
ETOTI - escaped weight total  
TTOTI - transmitted weight total
